## **Does Stock Price Synchronicity Represent Firm-Specific Information? The International Evidence**

### **ABSTRACT**

Much of prior international accounting research implicitly assumes that stock prices impound information with similar precision across countries. Recent research asserts that stock price synchronicity, defined as the  $R^2$  from asset pricing regressions, is a useful measure of the amount of information reflected in stock prices. This paper investigates the validity of the information-based interpretation of stock price synchronicity in international markets. The results of our analyses provide little support for using stock price synchronicity as a measure of information internationally. We develop an alternative measure of information based on the percentage of zero return days, i.e., zero-return metric, and repeat the analyses. Overall, our results suggest that the zero-return metric is a better measure of the relative amount of information impounded into share prices than the synchronicity measure in international markets.

## **Does Stock Price Synchronicity Represent Firm-Specific Information? The International Evidence**

### *1. Introduction*

Prior research documents differences in the value relevance, timeliness, and conservatism of accounting information across countries (see e.g., Alford, Jones, Leftwich, and Zmijewski 1993; Ball, Kothari, and Robin 2000; Ball, Robin, and Wu 2003). An underlying assumption of this line of research is that stock prices impound information with similar precision across countries. Morck, Yeung, and Yu (2000) propose that stock price synchronicity, defined as the  $R^2$  from asset pricing regressions, can be used as a measure of the relative amount of firm-specific information reflected in returns internationally. There are significant differences in mandated and voluntary information flows, ownership structures, trading activity, and market frictions across countries, that affect the price formation process in international markets. If stock returns do not capture information with the same precision across countries, then stock price synchronicity is limited in its use as a measure of the information reflected in stock prices internationally. In this paper, we investigate the extent to which the stock price synchronicity measure, i.e., the  $R^2$  measure, is associated with firm-specific information in the international setting.

Morck et al. (2000) interpret higher  $R^2$  values, i.e., greater stock price synchronicity, as returns that reflect more market-wide information and lower  $R^2$  values as returns that reflect more firm-specific information. We evaluate this interpretation of the synchronicity measure by conducting five analyses using data from six of the largest equity markets; Australia, France, Germany, Japan, the U.K., and the U.S.<sup>1</sup> Our first analysis builds on the work of Durnev, Morck, Yeung, and Zarowin (2003) who assess whether the  $R^2$  measure is associated with the informativeness of U.S. firms' stock prices. If the  $R^2$  measure consistently reflects firm-specific information in returns internationally, we expect lower  $R^2$  values to be associated with more informative prices with respect to future earnings. Overall, the results are not consistent with this

---

<sup>1</sup> The Appendix displays the summary findings in 15 additional countries that have sufficient data to conduct our five analyses.

expectation. We find lower  $R^2$  values are associated with more informative prices in Australia. However, we find higher  $R^2$  values are associated with more informative prices in Germany, Japan and the U.S., and find no statistically significant association between future earnings and returns conditional on  $R^2$  values in France or the U.K. Thus, in contrast to Durnev et al. (2003) who suggest that greater firm-specific return variation is associated with more informative stock prices in the U.S., our results suggest that there is no consistent relation between the  $R^2$  measure and the pricing of future earnings information internationally.<sup>2</sup>

Our second analysis investigates whether stock price synchronicity is associated with analyst forecast errors. Prior research documents a negative relation between firm disclosures and analysts' forecast errors (Lang and Lundholm 1996, Hope 2003). The work of Ashbaugh and Pincus (2001), and Lang, Lins, and Miller (2003) indicates that analysts' forecasts errors decline when a non-U.S. firm's public information set expands due to providing additional disclosures as a result of adopting International Financial Reporting Standards or U.S. Generally Accepted Accounting Principles, respectively. Therefore, if low  $R^2$  values reflect greater amounts of firm fundamentals being capitalized into share prices following the release of firm-specific information, we expect a positive relation between analysts' forecast errors and the  $R^2$  measure. The results are consistent with this expectation in Japan, where we document a positive association between the  $R^2$  measure and analyst forecast errors. In Australia, France, Germany, the U.K., and the U.S., however, we find that firms with higher  $R^2$  values have lower analyst forecast errors. These findings contradict the notion that the synchronicity measure consistently captures the relative information reflected in returns in international markets.

---

<sup>2</sup> Durnev et al. (2003) use a matched pair design and additional controls in the U.S. to assess whether firms with lower  $R^2$  are associated with more future earnings information reflected in returns. While the use of the matched paired design has advantages, the results potentially do not address the average cross-sectional relation between the  $R^2$  and future earnings information in the market. Since we are interested in assessing the association between the  $R^2$  measure and the pricing of future earnings within the respective market, we use a cross-sectional design. Thus our results speak to the sensitivity of the Durnev et al. (2003) findings to alternative design choices. Morck et al. (2000) view the  $R^2$  as a summary measure of the amount of information reflected in returns, under this interpretation the inclusion of control variables, such as size, which influence both the  $R^2$  measure and the pricing of future earnings information is not appropriate.

In our third analysis, we investigate whether there is a change in stock price synchronicity surrounding firms' cross listing in the U.S. Cross listing in the U.S. represents a major information event in that U.S. foreign registrants are required to provide more disclosures relative to the disclosures required in home markets (Ashbaugh 2001, Lang et al. 2003), and, in general, are more visible to new investors, which increases investors' information search (Karolyi 2004). If lower  $R^2$  measures represent relatively more firm-specific information in returns, we expect a decline in  $R^2$  values following firms' cross listing in the U.S. We find no evidence that Australian, French, German, Japanese, or U.K. firms'  $R^2$  values declined following cross listing in the U.S. Rather, we find that the  $R^2$  values of firms domiciled in France and the U.K. increased after a U.S. listing. The results of this analysis raise further doubt on whether the synchronicity measure can be used to capture differences in information impounded in stock price internationally.

Our fourth analysis tests the association between the synchronicity measure and variables that prior research uses to proxy for firm-specific information flows and firm fundamentals. Specifically, we use the reporting of a loss, the disclosure of research and development costs, analyst following, and the percentage of closely held shares to proxy for the quantity and quality of firms' information flows, and the standard deviation of sales and return-on-assets to proxy for firm fundamentals. If stock price synchronicity measures the relative amount of firm-specific information reflected in prices internationally, we expect consistent relations between  $R^2$  values and the variables that proxy for firms' information flows (fundamentals) across our sample countries. After controlling for firm size, turnover, and industry regulation, we find significant associations between the  $R^2$  measure and the information proxies (firm fundamentals) across countries. However, the associations are inconsistent in that we find positive relations between the  $R^2$  measure and information proxies (firm fundamentals) in some countries and negative relations in other countries. These findings provide additional evidence that the information-based interpretation of the  $R^2$  measure is not valid on a consistent basis in international markets.

The work of Andrade et al. (2005), Barberis et al. (2005), Kumar and Lee (2005), and Greenwood (2005), suggests that non-fundamental factors affect firms' stock price synchronicity. Building on Barberis et al. (2005), we conduct one more analysis that examines the association between German firms' membership in a German-market index and their  $R^2$  values. The German market provides a unique setting to assess the usefulness of the synchronicity measure as a measure of information because membership in certain German indices during our analysis period requires firms to provide additional disclosures that are intended to increase firm-specific information flows.<sup>3</sup> If the synchronicity measure reliably reflects the amount of firm-specific information, we expect the  $R^2$  values of German firms that are members of an index to be lower than other German firms. Contrary to the information-based explanation for the synchronicity measure, we find that membership in a German index is associated with significantly higher  $R^2$  values. These results suggest that non-fundamental factors significantly influence stock price synchronicity in the German market. Collectively, the results of our set of analyses suggest that the variation in firms' synchronicity measures internationally does not consistently capture differences in firm-specific information flows.

Having provided evidence that the information-based interpretation of the synchronicity measure is not reliable in international markets, we develop and investigate whether an alternative market measure better captures the relative amount of information in returns internationally. Building on the work of Bekaert, Harvey, and Lundblad (2003) and Lesmond, Ogden, and Trzcinka (1999), we use the percentage of zero-return days as a simplified measure of firm-specific-information. Lesmond et al. (1999) note if the value of an information signal is insufficient to exceed the costs of trading, then the marginal investor will not trade. If the marginal investor does not trade, then there is no change in price, and a zero return results. We apply this notion to the international setting assuming that when sufficient information arrives in

---

<sup>3</sup> We limit this analysis to the German market because of the difficulty in identifying non-U.S. firms' index memberships over time.

the market, investors trade, and a return is generated. Therefore, we conjecture that the proportion of zero returns days (hereafter referred to as the zero-return metric) represents the frequency of information arrival, where a lower zero-return metric (i.e., smaller proportion of zero-return weeks) reflects more informationally efficient share prices.

We repeat our five analyses using the zero-return metric in place of the synchronicity measure and find the following. In assessing whether the zero-return metric is associated with more informative prices with respect to future earnings, we find, as expected, that the zero-return metric is negatively associated with the amount of earnings related information reflected in returns in France, Germany, Japan, the U.K., and the U.S. Consistent with expectations, the results of the analyst forecast error analysis indicate that the zero-return metric is positively associated with analysts forecast errors in Australia, France, the U.K., and the U.S. In addition in France and the U.K. we find a significant decline in the zero-return metric following firms' cross listing in the U.S. When we regress the zero-return metric on information proxies and firm fundamentals, we find the relations between the zero-return metric and information proxies and fundamentals to be consistent with expectations. Based on the results of these analyses, we conclude that the zero-return metric is a better measure of the relative amount of information impounded in share prices than the  $R^2$  measure internationally.

Our study makes several contributions to the literature. First, the results of our study suggest that lower stock price synchronicity does not capture the amount of firm-specific information reflected in stock prices in international markets. Morck et al. (2000) document that stock prices move together more in poor countries relative to rich countries, and state that cross-country differences in property rights explain the cross-country variation in stock price synchronicity. Morck et al. (2000) conclude that strong property rights promotes informed arbitrage, which capitalizes detailed firm-specific information into prices leading to lower stock price synchronicity. The analysis and inferences drawn from Morck et al. (2000) are based on aggregate country-level measures, i.e. the country averages. As discussed by Freeman (2004),

Freedman, Pisani, and Purves (1998) and Greenland and Robbins (1994) using aggregate data as opposed to firm-specific data can result in different and potentially incorrect inferences being drawn. While the Morck et al. (2000) results speak to aggregate differences across countries, their analysis does not allow them to disentangle whether the synchronicity measure reflects firm-specific information within a country and, consequently, whether the synchronicity measure captures common information across countries. Our study measures and assesses  $R^2$  values at the firm level within a country. By examining the properties of the synchronicity measure across firms within a country we hold market micro-structure and institutional features, which potentially affect security pricing, constant thereby allowing us to test whether differences in the synchronicity measure within a country reflect more information-laden stock prices. The results of our firm-level analyses suggest that differences in synchronicity across firms are not driven by differences in information. Thus, we conclude that the information-based explanation for the synchronicity measure is not valid in internationally, and question whether across-market comparisons can be made using the synchronicity measure.<sup>4</sup>

Second, our research contributes to prior and concurrent research that investigates measures intended to capture the degree to which stock prices are informationally efficient (see e.g., Gelb and Zarowin 2002, Kelly 2005). We develop the percentage of zero return days, i.e., zero-return metric, as an alternative measure of information in returns that captures the degree to which prices are informationally efficient. Unlike other measures of information efficiency (e.g., the breadth of institutional ownership), the zero-return metric can be constructed for every firm listed in a public equity market. We provide evidence that the zero-return metric is a more reliable measure of information-laden stock prices than the synchronicity measure, and link the zero-return metric to factors that capture information flows and firm fundamentals. Having a

---

<sup>4</sup> Others have begun to assess the robustness of prior international research that draws inferences based on country-wide measures. For example, Holderness (2005) demonstrates the conclusions regarding the influence of weak legal institutions on ownership structure appear to be due to the use of aggregate (i.e., country-level versus firm-level) measures of ownership structure.

simple measure that captures differences in the degree of firms' price informativeness is important to researchers and regulators interested in the integration of capital markets as well as investors whose optimal resource allocation depends upon informationally efficient prices.

The paper proceeds as follows. Section 2 provides an overview of the prior literature on the  $R^2$  measure. Section 3 extends the findings of Morck et al. (2000) to our sample period. Section 4 reports the results of the analysis examining the  $R^2$  measure at the firm level. Section 5 describes the zero-return metric that we develop to capture the relative amount of information reflected in stock prices and reports the results of the analysis conducted using this new measure of firm-specific information. Section 6 reports the result of additional sensitivity analysis and Section 7 concludes the study.

## *2. Overview of the $R^2$ Measure and Related Literature*

Roll (1988) notes that typical asset pricing regressions yield relatively low explanatory power and proposes that one potential explanation for this is the incorporation of private, firm-specific information into prices.<sup>5</sup> Asset pricing models typically regress firms' returns on a set of common factors. For example, the capital asset pricing model (CAPM):

$$(1) \quad RET_{it} = \beta_{0,i} + \beta_{1,i} RETMKT_t + \varepsilon_{it}$$

where  $RET_{it}$  is the firms'  $i$  return for period  $t$  and  $RETMKT_t$  is the return on the market for period  $t$ . For this model to yield a high explanatory power the firm in question must trade with the market, meaning its share price must align with the share prices of other firms in the market, i.e., it must exhibit synchronous stock price movements.

The conventional interpretation of the residual from equation (1) is that after removing the return effects due to systematic factors, the remaining return volatility is due to idiosyncratic, firm-specific events. A low  $R^2$  from equation (1) is potentially due to firms' returns capturing

---

<sup>5</sup> The decline the  $R^2$  values overtime was documented by research prior to Roll (1988). Blume (1968), King (1966) and Officer (1971) all find a decline in the explanatory power of the market model overtime. Roll (1988), however, was the first to propose and investigate differences in  $R^2$  values across firms due to differences in the amount of firms-specific information reflected in prices information.

unique firm-specific information or reflecting greater idiosyncratic noise in returns. Roll (1988) notes that the incorporation of firm-specific information into prices generally increases the volatility of an individual firm's stock price, which results in lower explanatory power from asset pricing regressions such as equation (1). He finds that the low  $R^2$  from asset pricing models are primarily due to high firm-specific returns volatility and that this volatility is not associated with public news announcements. Based on this finding Roll contends that "private information or else occasional frenzy unrelated to concrete information" (p. 566) is driving the high firm-specific return volatility.<sup>6</sup>

Morck et al. (2000) is the first in a series of papers to use measures capturing the degree to which stock prices move together as a measure of the relative amount of firm-specific information reflected in stock prices. Using country level measures of stock price synchronicity, Morck et al. (2000) find that stock prices in poorer countries with less developed equity markets, weaker protection of investor rights, and weaker legal regimes tend to move together more. Morck et al. (2000) conclude that stronger protection of investor rights promotes informed trading resulting in more informative stock prices as evidenced by less synchronous trading in these countries.

Jin and Myers (2005) confirm the findings of Morck et al. (2000) and document a decline in country level  $R^2$  values overtime across a sample of 40 countries. In addition, Jin and Myers (2005) find that countries with higher  $R^2$  values experience more frequent market crashes and that the higher  $R^2$  values and more frequent crashes both result from more opaque information environments. Li, Morck, Yang, and Yeung (2004) investigate the behavior of country level measures of stock price synchronicity in emerging markets finding that  $R^2$  values are generally declining overtime and lower  $R^2$  values are associated with greater capital market openness, more

---

<sup>6</sup> One potential way in which firm-specific information is impounded into prices is through the actions of traders with private information about firm fundamentals. Actions undertaken by informed market participants such as analysts or insiders will result in firm-specific stock price movements, thus providing a potential explanation for high firm-specific returns volatility.

efficient legal systems and less corrupt economies. While the country level results of Morck et al. (2000), Jin and Meyers (2005) and Li et al. (2004) are consistent with an information-based interpretation of the  $R^2$  measure, the results do not address whether the synchronicity measure reflects informationally efficient prices at the firm level.<sup>7</sup>

Research examining whether the synchronicity measure reflects information efficient prices at the firm level has focused on the U.S. setting. One line of research builds on the fact that firm-specific information is impounded into prices through the public disclosure of information or through the actions of informed market participants. Durnev et al. (2003) examine whether firms with low synchronicity are associated with more future earnings information being reflected in returns. They find that U.S. firms with lower  $R^2$  values have more future earnings information reflected in stock prices, consistent with differences in synchronicity across firms being due to differences in the amount of information reflected in prices. Piotroski and Roulstone (2004) test the association between synchronicity and actions of informed market participants (i.e., analysts, institutional investors, and insiders).<sup>8</sup> They find that actions undertaken by informed market participants are associated with firms' stock price synchronicity. Finally Durnev et al. (2004) investigate whether firms with lower  $R^2$  values in the U.S. make better capital allocation decisions. They find that firms with lower  $R^2$  values tend to make more efficient investments (less over or under investment). Their finding is consistent with the synchronicity measure representing firm-specific information, in that firms with lower  $R^2$  values suffer from fewer problems with asymmetric information improving the coordination between capital suppliers and the firm, resulting in more efficient investments by the firm.

---

<sup>7</sup> As noted by Piotroski and Roulstone (2004, p. 1126) "traditional differences at the country level are not likely the cause of observed differences in synchronicity. Instead, differences in  $R^2$ 's are a result of the economics underlying each firm and the relative flow of information into prices."

<sup>8</sup> Chan and Hameed (2005) investigate the association between the  $R^2$  measure and analyst following in emerging markets, and find that higher analyst following is associated with higher  $R^2$  values. They interpret their findings as being consistent with analyst impounding market wide (not firm-specific) information into returns.

Another line of U.S. research explores whether low  $R^2$  values are a result of excess noise-in-returns resulting from other factors unrelated to firm fundamentals. Shiller (1981) and West (1988) find that the level of stock price volatility is too high to be explained by the volatility in the underlying fundamentals, e.g. dividends. West (1988) provides a theoretical model where increased firm-specific return volatility is associated with less firm-specific information and more noise-in-returns. In West's (1998) model relatively more information results in prices being closer to fundamental values, and the release of new information results in smaller price movements and lower firm-specific return volatility. West (1988) empirically tests his model and reports results that indicate that firm-specific return volatility is positively associated with bubbles, fad, and other non-fundamental factors.

Other studies suggest that behavioral factors, bubbles, herding and other non-fundamental factors affect stock price volatility (see Shleifer 2000 for a review), and ultimately the usefulness of the synchronicity measure as gauge of firm-specific information. Barberis et al. (2005) find significant changes in firms'  $R^2$  values surrounding additions and deletions to the S&P 500 index in the U.S., consistent with market frictions influencing synchronicity.<sup>9</sup> In addition, Greenwood and Sosner (2002), and Greenwood (2005) find similar results in Japan using additions and deletions from the Nikkei 225 index. Since additions and deletions to indices do not signal new information to the market regarding firms' fundamentals, the changes in firm's  $R^2$  values surrounding changes in the composition of indices is inconsistent with an information-based explanation of the  $R^2$  measure.

Kumar and Lee (2005) find that noise traders (uninformed retail investors) influence stock price synchronicity. Their findings are consistent with the noise in returns explanation for the  $R^2$  measure. Andrade et al. (2005) develop a model in which trading imbalances combined

---

<sup>9</sup> Barberis et al. (2005) develop a model to explain the changes in  $R^2$  values based on market frictions and sentiment. Both their empirical and theoretical work provides evidence inconsistent with the information-based explanation of the  $R^2$  measure.

with limited risk bearing capacity of arbitrageurs results in correlated price movements across stocks. An important feature of their model is that synchronous price movements result from cross stock price pressure, not information. Andrade et al. (2005) test their model in Taiwan and their results indicate that limited risk bearing capacity on the part of arbitrageurs can explain a significant portion (more than 50%) of observed stock price synchronicity, which is inconsistent with the information-based interpretation of synchronicity. Thus, the findings of Andrade et al. (2005), Barberis et al. (2005), Greenwood and Sosner (2002), Greenwood (2005), and Kumar and Lee (2005) indicate that market frictions, i.e., factors unrelated to information, have a significant influence on stock price synchronicity.

Campbell, Martin, Malkiel, and Xu (2001) document the rise in firm-specific return volatility in the U.S. overtime and the resulting decrease in  $R^2$  values. They interpret their findings in the spirit of West's (1988) model contending that the decrease in  $R^2$  values is not likely a result of increased firm-specific information. Wei and Zhang (2004) investigate the potential causes for increased firm-specific volatility overtime in the U.S., and find that the variance of firm fundamentals (return on equity) has increased overtime thereby providing a partial explanation for the findings of Campbell et al. (2001). However, Wei and Zhang further document that the increase in volatility of firm fundamentals and the association between fundamental volatility and return volatility is driven, for the most part, by newly listed firms, casting doubt on an information-based explanation for declining  $R^2$  values.

Rajgopal and Venkatachalam (2005) document a positive association between information risk, as measured by accrual quality and analyst forecast dispersion, and firm-specific returns volatility. Their findings are consistent with the theoretical work of Pastor and Veronesi (2003), who demonstrate that uncertainty about firms' fundamentals (information risk) influences returns volatility. These studies provide further evidence against the information-based interpretation of the synchronicity measure. If greater firm-specific returns volatility is associated

with poorer quality information (greater uncertainty) then how can higher firm-specific return volatility also be associated with more firm-specific information being reflected in returns?

Overall theoretical and empirical studies provide little support for the information-based interpretation of the synchronicity measure. In addition, arguments related to the limits and risk of arbitrage indicate that firm-specific return volatility may hinder informed trading rather than be a consequence of informed trading as claimed by Roll (1988) and Morck et al. (2000).

Subsequent international research tends to assume that Morck et al.'s (2000) country-wide measure of stock price synchronicity is a measure of the relative amount of firm-specific information reflected in firms' stock prices.<sup>10</sup> To date, however, we know of no evidence that validates the information-based explanation for the synchronicity measure internationally.

### 3. Replication

We measure a firm's stock price synchronicity following Morck et al. (2000) who define synchronicity as the percent of the variation in a firm's stock returns explained by variations in the firm's domestic market return and the U.S. market return. Specifically, the synchronicity measure is the  $R^2$  from estimating the following firm-specific regression:

$$(2) \quad RET_{it} = \beta_{0,i} + \beta_{1,i} RETMKT_{ct} + \beta_{2,i} RETMKTUS_t + \varepsilon_{it}$$

where  $RET_{it}$  is the return for firm  $i$  for the two week period  $t$ ,  $RETMKT_{ct}$  is the return on the market for country  $c$  for period  $t$ , and  $RETMKTUS_t$  is the return on the US market over period  $t$ .<sup>11</sup>

Like Morck et al. (2000), we use bi-weekly returns to deal with infrequent trading in international markets. We use value weighted market returns, where all returns, including the return on the U.S. market, are calculated in the local currency and are collected from *Datastream*. We estimate equation (2) by firm over the 52 week period encompassing the firm's fiscal year. We require

---

<sup>10</sup> For example, Wurgler (2000) examines the association between country-level measures of stock price synchronicity and country-level measures of the efficiency of capital allocations, and DeFond and Hung (2004) investigate the association between country-level synchronicity measures and CEO turnover internationally.

<sup>11</sup> For the U.S. sample we include only the return on the U.S. market in equation (2).

firms to have a minimum of 30 weeks of non-zero returns to estimate equation (2). To deal with extreme returns, we exclude all return observations with absolute values greater than 0.25 (Morck et al. 2000).<sup>12</sup> The country-level synchronicity measures are defined as:

$$(3) \quad R_{c,t}^2 = \frac{\sum_i R_{i,c,t}^2 \times SST_{i,c,t}}{\sum_i SST_{i,c,t}}$$

where  $SST_{i,c,t}$  is the total sum of squared variations from the firm-specific estimates of equation (2) within each country.

Panel A of Table 1 reports the descriptive statistics for the country-wide  $R^2$  measures of 21 developed equity markets, where all firm-year observations relate to firms that have sufficient data to estimate equation (2). We select these 21 countries because they are a subset of the countries studied by Morck et al. (2000) that have firms with sufficient accounting and market data to be included in our empirical tests.<sup>13</sup> For brevity, however, we table and discuss only the results of our empirical tests for Australia, France, Germany, Japan, the U.K., and the U.S. The Appendix summarizes our findings in the 15 other countries.

Panel A of Table 1 reports the mean (median) values of the  $R^2$  measure presented in order of average country rank. To calculate the average country rank, each year we rank the 21 sample countries by their  $R^2$  value and report the average country rank across the 13 sample years. The U.S. reports the lowest mean and median  $R^2$  values (mean value of 0.113 and median value of 0.097) as well as the lowest mean country rank of 1.615, followed by the Canada, Australia and

---

<sup>12</sup> Including these return observations does not change any inferences drawn from the results.

<sup>13</sup> To be included in the analysis presented in Table 1 we only require firm-year observations to have sufficient weekly returns data to calculate the  $R^2$  measure and to be on Worldscope. The requirement that firm-year observations are on Worldscope reduces our sample sizes compared to Morck et al. (2000). However this requirement ensures that firm-year observations included in Panel A of Table 1 have the necessary financial information available to conduct our other empirical tests.

France. The highest mean country ranks are found in Spain (16.692), Italy (17.077), and Singapore (19.231).

Morck et al. (2000) report that wealthier countries (as measured by gross domestic product) with common law legal regimes, and with greater protection of investor rights have lower stock price synchronicity. To replicate Morck et al. (2000), we estimate the following OLS regression:<sup>14</sup>

$$(4) \quad R_{c,t}^2 = \beta_1 \text{LEGAL}_{c,t} + \beta_2 \text{RIGHTS}_{c,t} + \beta_3 \text{GDP}_{c,t} + \sum_{fye=1990}^{2002} \alpha_{fye} \text{YEAR}_t + \varepsilon_{i,t}$$

where LEGAL is equal to one if the country is classified as having a code law legal origin (La Porta et al. 1998). RIGHTS is equal to the investor rights index developed by La Porta et al. (1998), where countries receive one point for each of the following, allowing voting by mail, the requirement of investors to deposit their shares prior to shareholder meetings, if cumulative voting or proportional representation of minority shareholder on the board is allowed, if there are mechanisms in place to for oppressed minority shareholders, the minimum ownership required to call an extraordinary shareholder meeting, and if shareholders have preemptive rights. GDP is equal to the log of the per capita gross domestic product for the country year. YEAR is equal to a series of fiscal year fixed effects.

The first three columns in Panel B of Table 1 display the results of estimating partial forms of equation (4) where only one institutional variable and YEAR are included in the model due to the high correlation across the institutional variables. Considered in isolation, we find that countries having code law legal regimes and lower levels of investor rights have higher synchronicity values. However, when we estimate equation (4) with all three institutional features (the results of which are reported in column 4 of Panel B), we find only a significant positive coefficient on LEGAL. While, the country level results are consistent with the results presented in Morck et al. (2000), a country-level analysis does not differentiate between differences in  $R^2$  values across firms being due to firms' stock prices reflecting relatively more information about firm fundamentals or differences in  $R^2$  values across firms being due to non-fundamental factors resulting in greater noise in returns. In the next section, we explore the extent to which the

---

<sup>14</sup> All regressions are estimated including fixed-year effects, resulting in different intercept values for each fiscal year. We do not table the fiscal year intercepts, which in general are significant at conventional levels.

synchronicity measure is associated with factors that represent firm information flows and fundamentals in five of the largest international equity markets.

#### *4. Within-country Analysis of the Synchronicity Measure*

##### 4.1 SAMPLE AND DESCRIPTIVE STATISTICS

Panel A of Table 2 presents the descriptive statistics on the  $R^2$  measure estimated using all firm-year observations over 1990-2002 for Australia, France, Germany, Japan, the U.K., and the U.S. that have the necessary data to conduct our empirical tests. Our empirical tests require returns, collected from Datastream, and accounting data, collected from Worldscope. Firm-year observations meeting the data requirements result in sample sizes of 2,895, 5,368, 3,515, 23,528, 14,248, and 56,925 for Australia, France, Germany, Japan, the U.K., and the U.S., respectively. The sample sizes reported in Table 2 (e.g., Australia  $n=2,895$ ) are smaller than those reported in Table 1 (e.g., Australia  $n=2,895$ ) due to the additional data required for our tests. Japanese firms have the highest  $R^2$  values (mean=0.319, median=0.298) whereas the U.S. has the lowest  $R^2$  values (mean=0.118, median=0.067).

##### 4.2 EMPIRICAL TESTS

Our first analysis examines the association between the synchronicity measure and accounting measures of stock price informativeness. Earnings are one of the primary sources of firm-specific information, and differences in the amount of earnings information reflected in stock prices is one potential reason for differences in  $R^2$  values across firms. Collins, Kothari, Shanken, and Sloan (1994), Gelb and Zarowin (2002), and Lundholm and Myers (2002) use the amount of information about current and future changes in earnings reflected in returns as a measure of price informativeness. Durnev et al. (2003) use this definition of price informativeness to draw inferences on whether firm-specific stock price movements in the U.S. market reflect firm-specific information or increased noise in returns. They find lower  $R^2$  measures are associated with more price informativeness. We test the association between the  $R^2$

measure and the amount of information related to changes in current and future earnings reflected in stock prices by estimating the following regression equation:

$$(5) \quad ABRET_t = \beta_1 \Delta E_t + \beta_2 \Delta E_t * RR_t^2 + \beta_3 \Delta E_{t+1} + \beta_4 \Delta E_{t+1} * RR_t^2 + \beta_5 ABRET_{t+1} + \beta_6 RR_t^2 + \sum_{fye=1990}^{2001} \alpha_{fye} YEAR_t + \varepsilon_t$$

where  $ABRET_t$  is the market adjusted buy and hold return over fiscal year  $t$ .  $RR_t^2$  is equal to the decile rank of the  $R^2$  value, determined by ranking observations each year based on the  $R^2$  value within each of the five countries.  $\Delta E_t$  is equal to the change in net income before extraordinary items scaled by beginning of period market value of equity over fiscal year  $t$ .  $YEAR$  is equal to a series of fiscal year fixed effects.<sup>15</sup>

The  $ABRET_{t+1}$  term is included in the model to correct for the errors in variables problem identified by Collins et al. (1994). Collins et al. (1994) note that the correct specification of equation (5) would include the expected change in future periods' earnings. Since expectations are unobservable the actual changes in future periods' earnings is used, introducing an errors in variables problem which they demonstrate can be corrected by including next period's return in the model. Given the results of Durnev et al. (2003) in the U.S. we expect  $\beta_2$  and  $\beta_4$  to be negative and significant if lower  $R^2$  values are associated with more information about current and future changes in earnings being reflected in returns.

Table 3 displays the results of estimating equation (5). In all countries, we find a positive and significant coefficient on the current change in earnings. The results are more mixed with respect to the change in future earnings. In Australia, Japan and the U.K., the coefficient on the change in future earnings is positive and statistically significant whereas in France and Germany, however, the coefficient on the change in future earnings is negative and significant. Turning to the primary variables of interest, we find little evidence that the  $R^2$  measure consistently reflects firm-specific information being impounded into share prices. France and the U.S. are the only countries where the  $R^2$  measure is associated with the current change in earnings and returns.

---

<sup>15</sup> All analyses are estimated including year fixed effects. For brevity, we do not table the year intercept values.

However, inconsistent with expectations, higher  $R^2$  values in France and the U.S. are associated with more information about the current change in earnings being reflected in stock prices. When examining the results of interacting future earnings changes with the  $R^2$  measure, we find the interaction to be statistically significant in Australia ( $\beta_4=-0.020$ ,  $p\text{-value}=0.01$ ) indicating that lower  $R^2$  values are associated with more information about future earnings changes being reflected in returns. In Germany, Japan, and the U.S., however, the interaction is positive and significant at the 0.06 level or better indicating that higher  $R^2$  values are associated with more information about future earnings changes being priced.<sup>16</sup>

Overall the results presented in Table 3 indicate that lower  $R^2$  values are not associated with more earnings information being reflected in returns. Rather, we find higher  $R^2$  values are associated with more earnings information being priced in France, Germany, Japan, and the U.S., which is opposite of what is expected if differences in the  $R^2$  values reflect differences in the amount of firm-specific information reflected in returns.<sup>17</sup>

Our second analysis examines the association between the synchronicity measure and analyst forecast errors. Our inquiry is motivated by prior international and U.S. research examining the properties of analyst forecast errors. In general, this literature finds that better information in the form of additional firm disclosures is associated with lower forecast errors (Lang and Lundholm 1996, Ashbaugh and Pincus 2001, Hope 2003, Lang et al. 2003).

Following this line of literature, we expect a positive relation between analysts' forecast errors and the synchronicity measure if the synchronicity measure reflects information.

We test the association between firms'  $R^2$  values and forecast errors using the following equation:

---

<sup>16</sup> We repeat the analysis presented in Table 3 using the unranked  $R^2$  values in each of the five countries, the results of this analysis are similar to those presented in Table 3.

<sup>17</sup> Our findings are consistent, in part, with West's (1988) model. West (1988) claims that lower firm-specific return volatility, higher  $R^2$ 's, is associated with more information about firm fundamentals being reflected in stock prices.

$$(6) \quad F\_ERROR_t = \beta_1 RR_t^2 + \sum_{fye=1990}^{2002} \alpha_{fye} YEAR_t + \varepsilon_t$$

where  $RR_t^2$  is equal to the decile rank of the  $R^2$  value for fiscal year  $t$ .  $F\_ERROR_t$  is equal to the decile rank of  $|\text{EPS}_{\text{act}} - \text{EPS}_{\text{forecast}}| / |\text{EPS}_{\text{forecast}}|$  for fiscal year  $t$ , where  $\text{EPS}_{\text{act}}$  is the firm's actual earnings per share and  $\text{EPS}_{\text{forecast}}$  is the mean consensus earnings per share forecast. Analyst forecasts are provided by IBES.  $YEAR$  is equal to a series of fiscal year fixed effects.<sup>18</sup>

We estimate equations (6) without controls due to the fact that Morck et al. (2000) argue that the  $R^2$  measure is a summary measure of information and thus the inclusion of controls is not appropriate as the potential effects of the control variables are captured by the  $R^2$  measure.

Table 4 presents the results from estimating equation (6). In Japan, the coefficient on the  $RR^2$  term is positive and significant at the 0.00 level. This indicates that in Japan, consistent with the information-based explanation for the synchronicity measure, lower  $R^2$  values are associated with lower analyst forecast errors. In Australia, France, Germany, the U.K., and the U.S., however, we find the coefficient on the  $RR^2$  term to be negative and significant at the 0.01 level or better. These results are, in general, inconsistent with the  $R^2$  measure reflecting differences in the relative amount of firm-specific information. Thus, in the majority of our sample countries, we find that higher  $R^2$  values are associated with lower analyst forecast errors, which is opposite of what is expected if lower synchronicity measures reflect relatively more firm-specific information.

Our third analysis investigates whether there is a change in firms' synchronicity measures after cross listing in the U.S. Cross listing in the U.S. represents a significant information event as a U.S. listing subjects firms to increased regulation and disclosure requirements that result in more information about the firm being made available to investors (Ashbaugh 2001, Lang et al. 2003). Furthermore, cross listing in the U.S. increases firm visibility, increasing the investor base and subsequent information search by investors (see Karolyi (2004) for an overview). If

---

<sup>18</sup> The sample sizes in the analyst forecast errors test are further reduced due to the requirement that firms be followed by an analyst.

synchronicity is a function of firm-specific information, it follows that firms'  $R^2$  values are expected to decrease after they cross list in the U.S.

Table 5 presents the results of the cross listing analysis where we define the change in  $R^2$  values as the  $R^2$  value in the 12 months following the cross listing month minus the  $R^2$  value in the 12 months preceding the cross listing month.<sup>19</sup> Panel A of Table 5 presents the mean and median change in  $R^2$  measure ( $\Delta R^2$ ) for all cross listings over the 1990-2002 time-period. The  $\Delta R^2$  means in Australia (-0.020) and Japan (-0.003) are directionally consistent with the predictions, but are not statistically different from zero. In France and the U.K., however, the mean change in the  $R^2$  measures (0.080 and 0.055, respectively) are positive and significantly different from zero (at the 0.02 level or better). We find similar results when examining the median  $\Delta R^2$ , where statistical significance is assessed using the Wilcoxon rank sum test.

Panel B of Table 5 examines only the Level 2 and 3 ADR's since these types of cross listing are associated with the greatest information disclosures. The results presented in Panel B of Table 5 are similar to the results for cross listings as a whole. We find that in France and the U.K. the mean and median  $\Delta R^2$  are positive and statistically different from zero at the 0.02 level or better. None of the other  $\Delta R^2$  measures are significantly different from zero. Overall, the results presented in Table 5 indicate that cross listing in the U.S. is not associated with a decline in the  $R^2$  values as one would expect under an information-based interpretation of the synchronicity measure.<sup>20</sup>

Our last analysis uses the framework of Piotroski and Roulstone (2004) to test the extent to which firm-specific information and firm fundamentals are related to the  $R^2$  measure in

---

<sup>19</sup> Cross listing dates and the type of cross listing (e.g. Level 1, 2, 3 or Rule 144A) are provided by J.P. Morgan Chase & Co.

<sup>20</sup> We conduct two additional sensitivity tests. First, we repeat the cross listing analysis estimating equation (2) without the U.S. return due to the potential mechanical effect that cross listing may have on the coefficient on U.S. return. Second, we estimate an OLS fixed effects model for each country using a dummy variable to capture the post period. We draw similar inferences from the results of these two sensitivity tests.

international markets. Piotroski and Roulstone (2004) use U.S. firms'  $R^2$  values as a benchmark of firm-specific information incorporated into prices, and test the association between  $R^2$  values and variables proxying for firms' information environment. Based on their work, we estimate the following fixed effects model:

$$(7) \quad \begin{aligned} \text{SYNCH}_t = & \beta_1 \text{LOSS}_t + \beta_2 \text{R \& D}_t + \beta_3 \text{ANALYST}_t + \beta_4 \% \text{CLHLD}_t + \beta_5 \text{STDSALES}_t + \\ & \beta_6 \text{STDROA}_t + \beta_7 \text{REG}_t + \beta_8 \text{RELSIZE}_t + \beta_9 \% \text{MVE}_t + \beta_{10} \% \text{TURNOVER}_t + \\ & \sum_{fye=1990}^{2002} \alpha_{fye} \text{YEAR}_t + \varepsilon \end{aligned}$$

where  $\text{SYNCH}_t$  is equal to  $\log(R^2/(1-R^2))$  for fiscal year  $t$ ;  $\text{LOSS}$  is equal to one if net income before extraordinary items is negative, and zero otherwise;  $\text{R\&D}$  is equal to one if the firm reports a value for research and development expense, and zero otherwise;  $\text{ANALYST}$  is equal to the log of one plus the number of analysts making a forecast for fiscal year  $t$ 's earnings;  $\% \text{CLHLD}$  is the proportion of shares that are closely held as of the end of the fiscal year  $t$ ;  $\text{STDSALES}$  is the standard deviation of sales scaled by total assets over calculated requiring a minimum of three and maximum of five fiscal years;  $\text{STDROA}$  is the standard deviation of ROA calculated requiring a minimum of three and maximum of five fiscal years where ROA is equal net income before extraordinary items divided by fiscal year end total assets;  $\text{REG}$  is equal to one if the firm is a financial institution or utility;  $\text{RELSIZE}$  is the firm's sales divided total sales of its primary industry (2-digit SIC code);  $\text{MVE}$  is defined as the natural log of fiscal year end market value of equity;  $\text{TURNOVER}$  is the average weekly turnover (number of shares traded divided by number of shares outstanding) over the fiscal year; and  $\text{YEAR}$  is equal to a series of fiscal year fixed effects.

The dependent variable in equation (7),  $\text{SYNCH}$ , is the  $R^2$  measure transformed to create continuous variable that yields a dependent variable with a more normal distribution than the distribution of  $R^2$  values that are bounded by zero and one (Morck et al. 2000, Piotroski and Roulstone 2004). We use four variables to proxy for firms' information environment ( $\text{LOSS}$ ,  $\text{R\&D}$ ,  $\text{ANALYST}$ ,  $\% \text{CLHLD}$ ) and two variables to proxy for firm fundamentals ( $\text{STDSALES}$ ,  $\text{STDROA}$ ).  $\text{LOSS}$  is included in the model as the reporting of losses is a news event expected to be reflected in returns (Joos and Plesko 2005, Hayn 1995). Likewise, the reporting of research and development expenditures is also considered to be a news event reflected in returns (Aboody and Lev 2000).  $\text{R\&D}$  is an indicator variable identifying whether the firm discloses research and development expenditures. Research and development is a highly firm-specific investment and

the disclosure of research and development expenditures in many countries is a voluntary disclosure over our analysis period. The number of analysts following the firm, ANALYST, is included in the model as a proxy for the firms' information environment because higher analyst following is associated with richer information environments (Lang and Lundholm 1996, Bushman, Piotroski, and Smith 2005). If firms'  $R^2$  values serve as a measure of firm-specific information incorporated into prices, we expect negative coefficients on LOSS, R&D, and ANALYST.

We use the percent of shares that are closely shares, %CLHLD, to proxy for insider ownership (Himmelberg, Hubbard, and Love 2002, Lins and Warnock 2004). Greater insider ownership will result in lower  $R^2$  values when insiders are able to gather and trade on private information about firm fundamentals (Roll 1988). Alternatively, greater insider ownership may result in higher  $R^2$  values if insiders manipulate financial information transparency for the purpose of hiding their wealth extraction or if insiders are part of group ownership where group ownership and the coordinated actions within the group, such as financing other firms in the group, results in a common component to firm's fundamentals. Given the competing explanations, we make no prediction on the relation between %CLHLD and SYNCH.

The standard deviation of sales (STDSALES) and the standard deviation of return-on-assets (STDROA) are included in the model to capture the volatility of firm fundamentals. One potential reason for high firm-specific return volatility is the volatility of underlying fundamentals. Wei and Zhang (2004) find that within the U.S., greater volatility in firms' return on equity is associated with increased return volatility. We include both the volatility of return-on-assets and sales due to differences in income smoothing internationally and the potential influence of income smoothing on return-on-assets (Leuz, Nanda, and Wysocki 2003). If firms'  $R^2$  values reflect firm fundamentals being incorporated into prices, we expect negative coefficients on STDSALES and STDROA.

The remaining variables in equation (7) (REG, RELSIZE, MVE, and TURNOVER) serve as control variables. REG is used to control for the fact that all firms operating in a regulated industry face similar constraints due to regulation, and thus, their prices are expected to have high stock price synchronicity (Piotroski and Roulstone 2004). RELSIZE is used to control for a firm's industry presence. The larger market share that a firm has in its industry the more likely the firm's stock price drives industry returns. Therefore we expect a positive relation between RELSIZE and SYNCH.

We include MVE to control for firm size. Larger firms are generally associated with richer information environments indicating a negative association between firm size and  $R^2$  values. However, larger firms also potentially have more diversified operations resulting in these firms trading more in line with the market resulting in a positive association between firm size and the  $R^2$  measure. We include TURNOVER in the model to capture the level of trading in a firm shares. Under the information based interpretation of the  $R^2$  measure, the association between the  $R^2$  measure and TURNOVER would be negative as more trading represents increased information being impounded into firms share prices. However if one assumes the  $R^2$  measure proxies for noise trading, trading unrelated to fundamentals, then the association between the  $R^2$  values and TURNOVER is expected to be positive. Given the uncertainty, we make no prediction of the sign of the coefficients on MVE and TURNOVER.

Panel A of Table 6 displays the Pearson correlations between synchronicity and the independent variables of equation (7). In general, there is quite a bit of variation across countries in the sign and significance of the correlations between firms'  $R^2$  values and the variables proxying for firms' information flows and fundamentals. In contrast, the correlations between the synchronicity measure and the control variables drawn from prior research are more consistent across countries.

Panel B of Table 6 presents the result of estimating equation (7) within each of our six countries. In general, the explanatory power of the model is similar across countries ranging

from a low of 14% in the U.S. to a high of 25% in Germany. The last two columns in Table 6 summarize the signs and significance of the estimated coefficients on the independent variables. The results indicate that in Japan, the U.K. and the U.S. LOSS is significantly associated with SYNCH. However, in Japan and the U.K. the coefficient on LOSS is significantly positive, which is contrary to what is predicted if the  $R^2$  measure reflects firm-specific information. Likewise, in four countries the coefficient on R&D is significantly positive, which is opposite of what is predicted. The results are mixed on ANALYST. As predicted the coefficient on ANALYST is negative and significant in the U.K. In contrast, the coefficient on ANALYST is positive and significant in the other five countries. These results indicate that the  $R^2$  measure is not consistently associated with variables that prior research has used to proxy for firms' public information environment.

Focusing on the impact of insider ownership on stock price synchronicity, the results indicate a significant negative association between %CLHLD and SYNCH in all five countries in which we have closely held ownership data. This finding supports the claim that insiders in these markets are able to gather private information about firm fundamentals (Roll 1988). Turning to the specific variables representing firm fundamentals, we find inconsistent relations between STDSALES and SYNCH across our sample countries. Specifically, the coefficient on STDSALES is significantly positive in Australia, France, Germany, and the U.S., and marginally significant and negative in the U.K. The coefficient on STDROA is only significant in two countries, Germany and Japan, and the sign is positive rather than negative as predicted if the  $R^2$  measure represents firm-specific information being impounded in share prices. The inconsistent results related to information environment variables and the volatility of firm fundamentals is particularly troubling for an information-based explanation of the  $R^2$  measure across countries.

Summarizing the findings on the control variables, we find mixed results on REG and RELSIZE is positively associated with SYNCH in only Australia. We find a positive and significant association MVE and SYNCH in all countries, which is consistent with the results of

Piotroski and Roulstone (2004) in the U.S. In four out of the six countries, France, Germany, the U.K., and the U.S., we find a significant positive association between the  $R^2$  and TURNOVER. Overall the results of the determinant model are relatively mixed across countries with the exception of the U.K., where the signs and significance of the coefficients are most consistent with expectations related to the  $R^2$  measure proxying for differences in the amount of firm-specific information reflected in share prices.

Barberis et al. (2005) and Greenwood and Sosner (2002) find that a firm's membership in an index increases its stock price synchronicity. Index membership may increase the  $R^2$  value due to market frictions and other non-fundamental factors (Barberis et al. 2005). To further investigate the link between stock price synchronicity and firm-specific information, we examine the association between German firms' index membership and SYNCH using the following model.

$$\begin{aligned}
 (8) \quad SYNCH_t = & \beta_1 LOSS_t + \beta_2 R \& D_t + \beta_3 ANALYST_t + \beta_4 \%CLHLD_t \\
 & + \beta_5 STDSALES_t + \beta_6 STDROA_t + \beta_7 REG_t + \beta_8 RELSIZE_t \\
 & + \beta_9 MVE_t + \beta_{10} TURNOVER_t + \beta_{11} DAX30_t + \\
 & \beta_{12} NEWMARKET_t + \beta_{13} NEMAX50_t + \sum_{fye=1990}^{2002} \alpha_{fye} YEAR_t + \varepsilon
 \end{aligned}$$

where DAX30 is equal to one if the firm is part of the DAX30 index in fiscal year t, and zero otherwise. NEMAX50 is equal to one if the firm is part of the NEMAX50 index in fiscal year t, and zero otherwise. NEWMARKET is equal to one if the firm's shares trades on the New Market in fiscal year t, and zero otherwise. All other variables are as previously defined.

We focus on German market indexes for two reasons. First, focusing on firms' membership in a German index provides a high powered setting to examine the effect of index membership on stock price synchronicity as firms' membership in some indexes in Germany requires increased information flows. Specifically, the New Market (NEWMARKET) is a segment of the Frankfurt Exchange that is of particular relevance to our study since listing in this segment required firms to provide additional information disclosures. Firms that list in the New

Market have to provide enhanced disclosures and follow stricter corporate governance policies. These requirements included the adoption of either International Financial Reporting Standards or U.S. generally accepted accounting principles, the publication of quarterly financial statements (only half-year reports are mandatory for other publicly traded German firms), regular analyst meetings, and the acceptance of the German code of corporate governance (a self regulatory set of rules aimed at strengthening the position of shareholders). If the synchronicity measure reflects the amount of firm-specific information captured in returns, we expect the coefficient on NEWMARKET to have a negative sign. On the other hand the New Market is known to be particularly bubble prone and was heavily covered by index oriented traders. Thus, if the  $R^2$  metric is influenced by non-fundamental information noise effects, we expect NEWMARKET to have a positive sign.

The other reason we limit this analysis to the German market is due to the difficulty in identifying non-U.S. index membership overtime. Limiting our analysis to one country ensures more reliable identification of index membership. We identify index membership by referring to the original historic index membership lists of the Deutsche Börse AG. The NEMAX50 is constructed using the 50 largest firms (measured by dispersed market capitalization) of the New Market segment of the Frankfurt Stock Exchange. The DAX30 comprises the 30 German companies which have the highest dispersed market capitalization.

Table 7 presents the results from estimating equation (8). With the exception of the coefficient on R&D, which is no longer significant, the results on the other independent variables are similar to those reported in Table 6 and are not discussed further. The coefficients on the three indicator variables identifying index membership are all positive and highly significant indicating that index membership is associated with higher  $R^2$  values. These results are consistent with the findings of Barberis et al. (2005) in the U.S. and Greenwood and Sosner (2002) and Greenwood (2005) in Japan. This finding is particularly important as it identifies other factors not related to firm fundamentals which significantly contribute to differences in

stock price synchronicity across firms. Finding that German firms' membership in an index is positively related to SYNCH is consistent with market frictions and/or market sediment, not information, being a significant determinant of stock price synchronicity.

In summary, the results presented in Tables 3 - 7 do not support the information-based interpretation of stock price synchronicity in international markets. Collectively, the results of our empirical tests suggest that using the  $R^2$  measure as a metric of firm-specific information internationally is not valid.

##### *5. An Alternative Measure of Firm-specific Information in Returns*

The arrival of new information about a firm in the market can generate new uncertainties and expectations regarding the firms' future cash flows. If the value of an information signal is insufficient to exceed the costs of trading, then the marginal investor will not trade (Lesmond et al. 1999). If the marginal investor does not trade, then no return is generated.<sup>21</sup> Building on this concept, we use the percent of zero return days (hereafter referred to as the zero-return metric) as an alternative measure of informational efficiency.<sup>22</sup> The zero-return metric is defined as is the number of zero return trading days over the fiscal year divided by the total trading days of the firms' fiscal year, where zero return days are days in which the price of the stock does not change compared to the price of the previous days.<sup>23</sup>

---

<sup>21</sup> Bekaert et al. (2003) and Lesmond (2005) use the percent of zero returns days as measure of liquidity internationally, and document that this measure is positively correlated with other more data intensive measures of liquidity. However Bekaert et al. note that one potential reason for a zero return unrelated to liquidity is a lack of news.

<sup>22</sup> The work of Easley, Kiefer, O'Hara, and Paperman (1996) in the U.S. supports our use of the percent of zero returns weeks as a measure of the frequency of information arrival. Specifically, they find that firms which trade more frequently (high volume firms) have a higher probability of information events relative to low volume firms, indicating that as expected the increased frequency of information arrival results in increased trading.

<sup>23</sup> By defining our zero return metric in this way, we classify daily observations with trade during the day but with identical beginning-of-day and end-of-day prices as zero return days, which may add additional noise to the measure. We believe that the probability of such an event is low because there are no tick size limitations in our sample countries. However, we test whether our results are sensitive to this design choice by alternatively defining our non-trading variable using the turnover data provided by *DataStream*. Our inferences remain unchanged when we use this alternative measure. We favor using price data rather than

Panel A of Table 8 presents the descriptive statistics on the zero-return metric for the six sample countries. Note that we use the same firm-year observations as in the empirical tests of the synchronicity measure to facilitate comparisons of the two measures. Both the mean and median values of the zero-return metric are largest in the U.K. (mean=0.505, median=0.554). The interpretation of this metric, for example, is that the average firm in the U.K. sample does not trade for 50.5% of the days in its fiscal year. The mean zero-return metric is 0.33 in Germany, followed by 0.331 in Australia, 0.300 in France, 0.264 in Japan and 0.195 in the U.S.

Panel B of Table 8 presents the Pearson and Spearman correlations between the zero-return metric and the synchronicity measure. In all six countries the correlations are significantly negative and the magnitude of the correlations are relatively large, in absolute terms, ranging from -0.262 in the U.S. to -0.473 in France. The consistently negative correlations indicate that lower  $R^2$  values are on average associated with a larger proportion of zero return weeks.

There are two potential explanations for the negative relation between the zero-return metric and stock price synchronicity. When a firm has more zero bi-weekly returns, then the number of observations used in estimating equation (2) is lower, which can reduce the explanatory power of the model resulting in a lower  $R^2$  value. At the same time, the zero-return metric will be moving towards one as there is a greater proportion of weeks where the firm's stock does not trade. The second potential reason for the negative correlations relies on infrequent, small, non-information-based trading. If some firms in a sample country trade relatively infrequently and in small amounts there is the potential for the bi-weekly returns to be driven by small somewhat immaterial trades. This will result in regressing relatively small bi-weekly returns on the market return producing a low  $R^2$  that is unrelated to firm-specific information.

---

volume data because in some countries, *DataStream* codes zero trading volume as zero while in other countries it presumably codes zero volume as missing values.

The empirical analyses described in the preceding section are a joint test of (1) the  $R^2$  measure reflecting differences in the relative amount of firm-specific information reflected in stock prices and (2) our empirical analyses being valid tests of the consequences or determinants of firm-specific information reflected in stock prices. To validate our empirical analyses as suitable tests and to provide evidence on whether the zero-return metric is a better measure of firm-specific information in returns, we repeat our empirical analyses substituting the zero-return metric for the synchronicity measure.<sup>24</sup>

Panel C of Table 8 displays the results of our price informativeness tests using the zero-return metric. Specifically, the association between the zero-return metric and the amount of earnings information reflected in stock prices is tested using the following equation:

$$(9) \quad ABRET_t = \beta_1 \Delta E_t + \beta_2 \Delta E_t * R\%ZR_t + \beta_4 \Delta E_{t+1} + \beta_5 \Delta E_{t+1} * R\%ZR_t + \beta_6 ABRET_{t+1} + \beta_7 R\%ZR_t + \sum_{fye=1990}^{2001} \alpha_{fye} YEAR_t + \varepsilon_t$$

where  $R\%ZR_t$  is equal to the decile rank of the zero return metric for fiscal year  $t$ , and all other variables are as previously defined.

If the zero-return metric captures the degree of firm-specific information reflected in returns we expect a negative association between the zero-return metric and the amount of earnings information reflected in returns. In all countries, we find that a larger portion of zero return weeks is associated with less information about the current change in earnings being reflected in returns. In France, Germany, Japan, the U.K., and the U.S. (Australia), we find that less (more) information about the change in next period earnings is reflected in returns when firms trade less frequently. The results presented in Panel C of Table 8 indicate that our simple zero-return metric is associated with the amount of earnings related information reflected in returns.

---

<sup>24</sup>As in the synchronicity tests, all analyses are estimated including year fixed effects. For brevity, we do not table the year intercept values.

Panel D displays the results of testing whether there is an association between the zero-return metric and analyst forecast errors using equation (10) below:

$$(10) \quad F\_ERROR_t = \beta_1 R\%ZR_t + \sum_{fye=1990}^{2002} \alpha_{fye} YEAR_t + \varepsilon_t$$

where all variables are as previously defined. If the zero-return metric represents firm-specific information we expect a positive association between the zero-return metric and analysts' forecast errors. Similar to the analysis using the synchronicity measure we estimate equation (10) without control variables as we view the zero-return metric as a summary measure of firm's information environments. The results indicate that in Australia, France, the U.K., and the U.S. larger zero-return metrics are associated with larger analyst forecast errors. We find no significant association between the zero-return metric and analysts' forecast errors in Germany and Japan. These findings are in contrast to those reported in Table 4, where we find inconsistent associations between  $R^2$  values and analysts' forecast errors across the sample countries.

Panels E and F of Table 8 presents the results of the cross listing analysis where we define the change in zero-return metric values as the zero return metric value in the 12 months following the cross listing month minus the zero-return metric value in the 12 months preceding the cross listing month.<sup>25</sup> Panel E presents the mean and median changes in for all cross listings over the 1990-2002 time-period. The only country for which the change in the zero return measure is significant is France where both the mean and median values indicate a decline in the zero-return measure following cross listing. Panel F examines only the Level 2 and 3 ADR's since these types of cross listing are associated with the greatest information disclosures. The results presented in Panel F indicate that in both France and the U.K. there is evidence indicating

---

<sup>25</sup> There is limited variance in the dependent variable in this analysis as cross-listed firms are, on average, large and well-traded, the level of zero-return days is low ex ante as well as ex post cross listing. In addition, it remains a matter of open debate whether cross listing indeed has a consistent impact on the participating firms' information infrastructure.

the firm's trade more frequently following cross listing in the U.S., the mean and median  $\Delta R^2$  are negative and statistically different from zero at the 0.01 level or better.

Our final analysis tests the extent to which firm-specific information and firm fundamentals are related to the zero-return metric in our sample countries. Panel G presents the results from estimating the following model:

$$(11) \quad \begin{aligned} \%ZERORET_t = & \beta_1 LOSS_t + \beta_2 R \& D_t + \beta_3 ANALYST_t + \beta_4 \%CLHLD_t + \beta_5 STDSALES_t \\ & + \beta_6 STDROA_t + \beta_7 REG_t + \beta_8 RELSALES_t + \beta_9 \%MVE_t \\ & + \beta_{10} \%TURNOVER_t + \sum_{fye=1990}^{2002} \alpha_{fye} YEAR_t + \varepsilon \end{aligned}$$

where  $\%ZERORET_t$  is equal to  $\log(\%ZR/(1-\%ZR))$  for fiscal year  $t$ , where  $\%ZR$  is the percent of zero return days.<sup>26</sup> All other variables are as previously defined.

The explanatory power of the zero-return metric model ranges from a low of 53% in Japan to a high of 78% in the U.S. In all countries the explanatory power of the zero-return metric model is higher than the explanatory power of the SYNCH model reported in Table 6. In general, the results displayed in Panel G of Table 8 suggest that the zero-return metric is a better indicator of firm-specific information reflected in returns. Specifically, the coefficient on  $LOSS_t$ , as expected, is negative and significant in Australia, Germany, Japan, the U.K., and the U.S. Likewise, we find a negative coefficient on  $R\&D_t$  in Australia, Germany, Japan, the U.K., and the U.S. We also find the coefficient on  $ANALYST_t$  to be consistently negative and the coefficient on  $\%CLHLD_t$  to be consistently positive across countries. Turning to the variables that proxy for firm fundamentals, we find that  $\%ZERORET_t$  is negatively associated with  $STDSALES_t$  and  $STDROA_t$  across countries, as expected. Overall the signs and significance of the control variables are also more consistent across countries. These findings provide additional evidence that suggests that

---

<sup>26</sup> In order to implement the log transformation, we modify  $\%ZR$  to be the amount of non-traded days plus 1 divided by the total number of days in the fiscal year plus 2.

the zero-return metric more appropriately captures the relative amount of information impounded into share prices than the synchronicity measure.<sup>27</sup>

Table 9 summarizes the results of our empirical analysis where we first use the firm-specific stock price synchronicity measure and then repeat the analysis using the zero-return metric. Based on the results of our empirical analysis, we conclude that a simple measure of firm's information environments based on trading activity better captures differences in the amount of information reflected in firms' returns than the stock price synchronicity measure.<sup>28</sup>

#### 6. *Additional Analysis*

To examine the robustness of our inferences, we make the following modifications to equation (2) in calculating the synchronicity measure: (1) use equal weighted returns; (2) drop the U.S. market return from equation (2); (3) include industry wide returns in equation (2), where industries are defined based on 2-digit SIC codes; (4) estimate equation (2) using weekly instead of bi-weekly returns; and (5) include lagged returns as additional explanatory variables. Overall, repeating the analysis with the alternative synchronicity measures results in similar inferences.

We also examine the influence of infrequent trading on the synchronicity measure as one potential explanation for why the synchronicity measure does not capture information. To investigate the effect of infrequent trading on the usefulness of the synchronicity measure, we conduct a sensitivity analysis where we modify the  $R^2$  measure to incorporate the effect of thin trading. Specifically, we calculate for each firm-year observation:

$$(12) R2TRADE_t = \frac{R_t^2}{1 - \%ZR_t(1 - R_t^2)}$$

---

<sup>27</sup> As a robustness test we use TURNOVER instead of the zero return measure and repeat the test in Tables 3-6. While performing better than the original  $R^2$  measure, TURNOVER does not perform nearly as well as the zero-return metric.

<sup>28</sup> We draw the same inferences when comparing the synchronicity results to the zero-return results across the 15 other countries that we examine. Appendix A summarizes the inferences drawn from the empirical analyses using firm-year observations from the other fifteen countries identified in Table 1.

where all variables are as previously defined. As %ZR approaches zero,  $R2TRADE_t$  becomes  $R_t^2$ , and as %ZR approaches one,  $R2TRADE_t$  becomes one. We repeat the analyses presented in Tables 3-6 using this modified  $R^2$  measure. The results are similar to what is reported in Tables 3 through 6. Thus, our additional analyses provide further evidence that the  $R^2$  measure does not appear to reflect differences in the informational efficiency of firms' share prices internationally.

### *7. Conclusions*

Morck et al. (2000) document differences in stock price synchronicity across countries claiming that these differences are due to the variation in property rights and the influence that property rights have on informed investors' trading incentives. Prior international research assumes that the country-level  $R^2$  values reflect the amount of information impounded in stock prices and uses this measure to explain cross-country differences in events of interest to finance and accounting researchers. This paper investigates the validity of the information-based interpretation of stock price synchronicity in non-U.S. markets. Collectively, the results of our analysis suggest that the variation in stock price synchronicity across firms in international markets is not due to differences in firm-specific information.

We offer the zero-return metric, defined as the percent of zero-return days, as an alternative measure of firm-specific information reflected in stock prices internationally. Based on the results of a multitude of tests, we conclude that the zero-return metric is more useful in capturing the differences in information environments across firms than the synchronicity measure. Contemporaneous research uses the percent of zero return days as a measure of liquidity, where smaller values represent more liquid stocks (Bekaert et al. 2005). Bekaert et al. (2005) document that in emerging markets the percent of zero return days is a priced risk factor. Easley and O'Hara (2005) provide a theoretical foundation for information being a priced risk factor. Thus, it is not clear whether the zero-return metric is impounded into share prices because

it proxies for liquidity or it proxies for information or both. Future research can further probe the usefulness of the zero-return metric in market analysis.

**Panel B: Institutional Explanations for R<sup>2</sup> Measure**

$$R_{c,t}^2 = \beta_1 \text{LEGAL}_{c,t} + \beta_2 \text{RIGHTS}_{c,t} + \beta_3 \text{GDP}_{c,t} + \sum_{fye=1990}^{2002} \alpha_{fye} \text{YEAR}_t + \varepsilon_{c,t}$$

	<u>1</u>	<u>2</u>	<u>3</u>	<u>4</u>
LEGAL	0.043***			0.052***
RIGHTS		-0.010***		0.010
GDP			0.003	-0.013
AdjR <sup>2</sup>	0.30	0.27	0.24	0.31
n	273	273	273	273

Variable definitions:

As in Morck et al (2000)  $R_{c,t}^2 = \frac{\sum_i R_{i,c,t}^2 \times SST_{i,c,t}}{\sum_i SST_{i,c,t}}$  where  $SST_{i,c,t}$  is the total sum of squared variations

and  $R_{i,c,t}^2$  is equal to the  $R^2$  from the following regression:

$RET_{it} = \beta_{0,i} + \beta_{1,i} RETMKT_{ct} + \beta_{2,i} RETMKTUS_t + \varepsilon_{it}$  for all countries but the U.S. For the U.S. we estimate the regression:

$$RET_{it} = \beta_{0,i} + \beta_{1,i} RETMKT_{ct} + \varepsilon_{it}$$

where  $RET_{it}$  is the return for firm  $i$  for the two week period  $t$ ,  $RETMKT_{ct}$  is the return on the market for country  $c$  for period  $t$ , and  $RETMKTUS_t$  is the return on the US market over period  $t$ . All returns are expressed in the local currency.  $LEGAL$  is equal to one if the country is classified as having a code law legal origin (La Porta et al. 1998).  $RIGHTS$  is equal to the investor rights index developed by La Porta et al. (1998), where countries receive one point for each of the following, allowing voting by mail, the requirement of investors to deposit their shares prior to shareholder meetings, if cumulative voting or proportional representation of minority shareholder on the board is allowed, if there are mechanisms in place to for oppressed minority shareholders, the minimum ownership required to call an extraordinary shareholder meeting, and if shareholders have preemptive rights.  $GDP$  is equal to the log of the per capita gross domestic product for the country year.  $YEAR$  is equal to a series of fiscal year fixed effects. Mean Rank is equal to the mean yearly rank for the country, where the 20 sample countries are ranked each year from 1990 to 2002. \*\*\*, \*\*, \* indicates significance at the 0.01, 0.05 and 0.10 levels two-tailed, respectively.

**TABLE 2**  
*Descriptive Statistics on Firm-Specific R<sup>2</sup> Measures*

<u>Country</u>	<u>25<sup>th</sup></u>	<u>Mean</u>	<u>Median</u>	<u>75<sup>th</sup></u>	<u>Std. Dev</u>	<u>n</u>
Australia	0.072	0.192	0.158	0.277	0.152	2,895
France	0.056	0.183	0.137	0.268	0.162	5,368
Germany	0.066	0.203	0.156	0.301	0.172	3,515
Japan	0.155	0.319	0.298	0.463	0.199	23,528
U.K.	0.072	0.217	0.168	0.315	0.183	14,248
U.S.	0.016	0.118	0.067	0.174	0.136	56,925

Variable definitions:

R<sup>2</sup> is equal to the R<sup>2</sup> from the following regression:

$$RET_{it} = \beta_{0,i} + \beta_{1,i} RETMKT_{ct} + \beta_{2,i} RETMKTUS_t + \varepsilon_{it} \text{ for all countries but the U.S. For the U.S.}$$

we estimate the regression:

$$RET_{it} = \beta_{0,i} + \beta_{1,i} RETMKT_{ct} + \varepsilon_{it}$$

where RET<sub>it</sub> is the return for firm i for the two week period t, RETMKT<sub>ct</sub> is the return on the market for country c for period t, and RETMKTUS<sub>t</sub> is the return on the US market over period t. All returns are measured in the local currency.

**TABLE 3**  
*The R<sup>2</sup> Measure and the Price Informativeness of Earnings*

Variable definitions:

ABRET<sub>t</sub> is the market adjusted buy and hold return over fiscal year t.  $RR_t^2$  is equal to the decile rank of the R<sup>2</sup> value for fiscal year t.  $\Delta E_t$  is equal to the change in net income before extraordinary items scaled by beginning of period market value of equity for fiscal year t. YEAR is equal to a series of fiscal year fixed effects.

**TABLE 4**  
*R<sup>2</sup> Measure and Analysts' Forecast Errors*

$$F\_ERROR_t = \beta_1 RR_t^2 + \sum_{fye=1990}^{2002} \alpha_{fye} YEAR_t + \varepsilon_t$$
